Fall velocity vs time when $v(0)=10($ in SI)

[ $>$ \# The same terminal velocity is achieved!
[ $>$ \# Get the accel. by derivative:
> a:=diff(V,t);
$a:=(10.000000000000+0 . \mathrm{I})(1-\tanh (1.4638501094228 t+0.83495951529394$
-1.5707963267949 I) $\left.{ }^{2}\right)$
[ $>$ plot (a,t=0..2, thickness=3,title="Acceleration vs time when parachute opens (in SI)");

Acceleration vs time when parachute opens (in SI)

\# If this was realistic (immediate opening of parachute, ie, area A goes from 0 to full, then the parachutist would undergo a massive stretch: before time zero s/he accelerates with g=10 $\mathrm{m} / \mathrm{s}^{\wedge} 2$ downwards (positive direction by choice), and then in one instant the acceleration switches to the opposite, $11 \mathrm{~m} / \mathrm{s}^{\wedge} 2$ in the upward direction! This would not be good for the body!
