Orbital debris

- Any man-made junk in orbit
- Whole defunct satellites, parts of spacecraft, launch vehicles, fragmentation debris
- 29,000 pieces > 10 cm diameter (they are tracked)
- 750,000 pieces 1 - 10 cm diameter
- 150 Mill pieces 0.1 - 1 cm , particularly very small pieces that cannot be tracked ➔ greatest risk to space missions
- Only a few satellite to satellite disasters so far
  - 2009: Russian military satellite – Iridium 2200 pieces were generated (tracked)

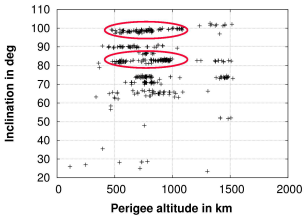
12

Which satellites are most likely to collide?



Collisions will mainly occur between sun-synchronous satellites (i ≈ 98°) and objects at i ≈ 82°. Basically head-on collisions with twice the orbital velocity!

Optical techniques

- A 1-meter diameter telescope in darkness can theoretically detect a sunlit metal sphere 1 cm in diameter at 900-km distance.
  - Unfortunately, most debris fragments reflect much less light than a metal sphere; typically only about 10 percent of the light is reflected.
  - In addition, objects in LEO have angular velocities of at least 0.5 degree per second when viewed from the ground, which further increases the difficulty of optical detection.
  - Finally, there can be difficulty in discriminating between debris and the luminosity caused by meteors interacting with the atmosphere. Theoretically, this last problem can be solved completely by using two telescopes and determining the object's altitude with the measured parallax, or solved partially by using the object's angular velocity to approximate its altitude.
- Despite these drawbacks, ground-based telescopes engaged in sampling have provided some valuable information on the LEO population of debris around 10 cm in diameter.
- Ground-based telescopes also can be used to sample the space debris population above LEO.

Adopted from Newland

20

Haystack observatory, MA, USA

NASA's primary radar for detecting space debris

21

Radar sampling

- Short-wavelength ground-based radars have been used effectively to sample the medium-sized debris population in LEO. Radars sample debris in a "beam park" mode in which the radar stares in a fixed direction (preferably vertically to maximize sensitivity) and debris are counted as it passes through the radar's field of view.
- In 1989, the Arecibo Observatory's high-power 10-cm-wavelength radar and the Goldstone Deep Space Communications Complex's 3-cm-wavelength radar were used (with the assistance of other radars) to obtain orbital debris data. Neither was designed to track debris, but in 18 hours of operation, the Arecibo experiment detected nearly 100 objects larger than an estimated 0.5 cm in diameter and in 48 hours of observation, the Goldstone radar detected about 150 objects larger than approximately 0.2 cm in diameter.
- Since 1987, significant amounts of sampling data have been obtained by using the Arecibo, Goldstone, and Haystack radars. In addition, the longer-wavelength FGAN and MU radars have demonstrated the ability to sample the medium and large debris population.

Adopted from Newland

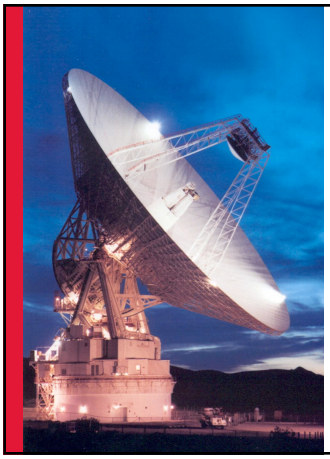
22

Radar sampling

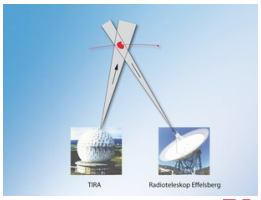
- The complete data set from the Haystack observations contains information on the size, altitude, range rate (the rate of change in the distance from the object to the radar), and direction of motion of debris at altitudes up to 1,500 km.
- The smallest objects detected range from about 0.3 cm at 350 km to 0.7 cm at 1,400 km.
- Most of the radars transmit right circularly polarized radio waves and receive both left and right circularly polarized waves. The polarization of the reflection can be used to infer the general shape of the objects detected.

Adopted from Newland

23



When used as bistatic Radar, antenna can detect 2 mm debris up to 1000 km altitude



24

Impact sampling

- Currently (and for the foreseeable future), space debris particles smaller than a few millimeters in diameter cannot be detected by using Earth-based measurement techniques; effective remote sensing of such particles from orbit may also be infeasible.
- In situ impact techniques, however, can be used to sample this population effectively, characterizing particle sizes and materials as well as orbital distributions and dynamics (although such characterizations can be extremely difficult).
- Such measurements can be performed either passively, by exposing surfaces in orbit and then returning them to Earth for examination, or actively, by using any of a number of techniques ranging from impact detection with simple semiconductor-based sensors to chemical composition analysis of impacting particles with complex sensors.

Adopted from Newland

25

Comparison of systems

- Note that with optical systems, the signal decreases as a function of the range squared, not as a function of the range to the fourth power as it does with radars.
- This makes optical systems more sensitive at longer ranges. Another consideration is the angular rate that the object image crosses the detector. For non-tracking telescopes where the telescope is not locked on to the object's motion, the image is spread over several pixels, thus decreasing the available signal for discrimination against the background level

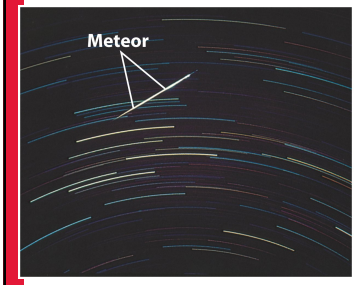
Terminology

Small rocks in space are called meteoroids



- If a meteoroid enters the Earth's atmosphere, it produces a fiery trail called a meteor
- If part of the object survives the fall, the fragment that reaches the Earth's surface is called a meteorite

30

An astronaut image of a Perseid meteor over Earth.

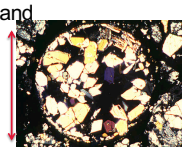
32

Meteorite classification

- Stones (like rocks on Earth)
  - Chondrites composed of chondrules. These are small spheres formed by rapid melting and subsequent rapid cooling. Radiometric age: 4.6 Bill. Years.
  - Achondrites – same minerals but chondrules destroyed because of later heating and melting and recrystallization.



- Irons (alloys of iron and nickel)
- Stony irons (stony silicates mixed with iron)

Image: http://www.lpi.usra.edu/science/kring/epo_web/meteorites/chondrule.html

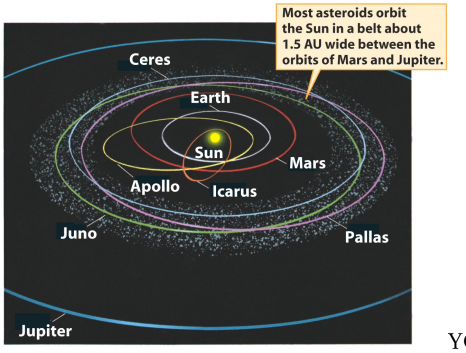
33

Origin of meteorites

- Asteroids
  - Collisions made fragments that found their way toward Earth
- Comets
  - Fragments and dust left behind – Earth crosses path
- Moon, Mars
  - Crustal rocks were catapulted into space when another object collided with Moon or Mars

34

Asteroid belt



N. F. Comins, Freedman

35

- Astronomers first discovered the asteroids while searching for a "missing planet"
- 100,000's of rocky irregularly shaped and cratered bodies orbit the Sun between Mars and Jupiter.
- 4000 asteroids are catalogued and their orbits are known.
- The largest asteroids are Ceres (1000 km diameter), Juno and Pallas.
- Some, called Appollo objects, have orbital paths that cross Earth's orbital path.
- Objects coming close to Earth are called Near Earth Objects (NEOs)
- ~150 NEO's (1 to 8 km diameter) are known. They have unstable orbits and eventually will collide with Earth.

51

Close encounters

- 1000 asteroids with size of >1 km cross Earth orbit. 30% will hit Earth eventually, 1 every 300,000 yr. Could kill 1 Bill people.
- 1178 Moon was hit. 20 km crater. 120,000 Mt explosion, 6 times Earth's atomic arsenal.
- 23 March 1989 asteroid 1989 FC missed Earth by 6 h. It was detected after passage. Explosion potential ~ 1000 nuclear bombs.
- 1908 Tunguska asteroid, size 50 m. Expectation: every 100 yr. Equivalent to 20 Mt H bomb.
- 1990 small asteroid into Pacific ocean. Explosion power: small atomic bomb.
