Abstract Response inhibition is essential for navigating everyday life. Its derailment is 27 considered integral to numerous neurological and psychiatric disorders, and more generally, to a 28 wide range of behavioral and health problems. Response-inhibition efficiency furthermore 29 correlates with treatment outcome in these conditions. The stop-signal task is an essential tool to 30 determine how quickly response inhibition is implemented. Despite its apparent simplicity, there 31 are many features (ranging from task design to data analysis) that vary across studies in ways that 32 can easily compromise the validity of the obtained results. Our present goal is to facilitate a more 33 accurate use of the stop-signal task. To this end, we provide twelve easy-to-implement consensus 34 recommendations and point out the problems that can arise when these are not followed. This 35 article is furthermore accompanied by user-friendly open-source resources intended to inform 36 statistical-power considerations, facilitate the correct implementation of the task, and assist in 37 proper data analysis. 38

40 Introduction

The ability to suppress unwanted or inappropriate actions and impulses ('response inhibition') is a 41 crucial component of flexible and goal-directed behavior. The stop-signal task (Lappin and Eriksen) 42 1966: Logan and Cowan. 1984: Vince, 1948) is an essential tool for studying response inhibition 43 in neuroscience, psychiatry, and psychology (among several other disciplines; see Appendix 1). 44 and is used across various human (e.g. clinical vs. non-clinical, different age groups) and non-45 human (primates, rodents, etc.) populations. In this task, participants typically perform a go task 46 (e.g. press left when an arrow pointing to the left appears, and right when an arrow pointing to 47 the right appears), but on a minority of the trials, a stop-signal (e.g. XX) appears after a variable 48 stop-signal delay (SSD), instructing participants to suppress the imminent go response (Figure 1). 49 Unlike the latency of go responses, response-inhibition latency cannot be observed directly (as 50 successful response inhibition results in the absence of an observable response). The stop-signal 51 task is unique in allowing the estimation of this covert latency (stop-signal reaction time or SSRT; 52 Box 1). This research has revealed links between inhibitory-control capacities and a wide range 53 of behavioral and impulse-control problems in everyday life (e.g., attention-deficit/hyperactivity 54 disorder, substance abuse, obesity, obsessive-compulsive behaviors, excessive risk-taking....). 55 Today, the stop-signal field is flourishing like never before (see Appendix 1). There is a risk. 56 however, that the task falls victim to its own success, if it is used without sufficient regard for a 57 number of important factors that jointly determine its validity. Currently, there is considerable 58 heterogeneity in how stop-signal studies are designed and executed, how the SSRT is estimated. 59 and how results of stop-signal studies are reported. This is highly problematic. First, what might 60 seem like small design details can have an immense impact on the nature of the stop process 61 and the task. The heterogeneity in designs also complicates between-study comparisons, and 62 some combinations of design and analysis features are incompatible. Second, SSRT estimates are 63 unreliable when inappropriate estimation methods are used or when the underlying race-model 64 assumptions are (seriously) violated (see Box 1 for a discussion of the race model). This can lead to 65

artefactual and plainly incorrect results. Third, the validity of SSRT can be checked only if researchers report all relevant methodological information and data.

Here we aim to address these issues by consensus. After an extensive consultation round. 68 the authors of the present paper agreed on twelve recommendations that should safeguard and 69 further improve the overall quality of future stop-signal research. The recommendations are based 70 on previous research or, where further empirical support was required, on novel simulations (which 71 are reported in Appendices 2–3). Below, we provide a concise description of the recommendations. 72 We briefly introduce all important concepts in the main manuscript and the boxes. Appendix 4 73 provides an additional systematic overview of these concepts and their common alternative terms. 74 Moreover, this article is accompanied by novel open-source resources that can be used to execute 75 a stop-signal task and analyze the resulting data, in an easy-to-use way that complies with our 76 present recommendations (https://osf.io/rmgaw/). The source code of the simulations (Appendices 77 2–3) is also provided, and can be used during the planning stage (e.g. to determine the required 78 sample size under varving conditions, or acceptable levels of go omissions and RT distribution 79

80 skew).

103 Results and Discussion

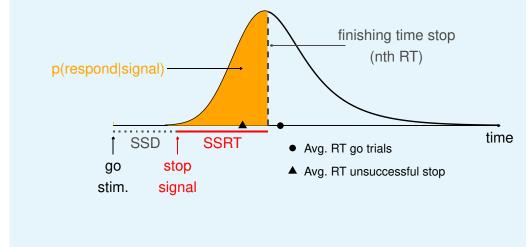

104 How to design stop-signal experiments

The following recommendations are for stop-signal users who are primarily interested in obtaining a reliable SSRT estimate under standard situations. The stop-signal task (or one of its variants) can also be used to study various aspects of executive control (e.g. performance adjustments or learning) and their interactions, for which the design might have to be adjusted. However, researchers should be aware that this will come with specific challenges (e.g. *Bissett and Logan,* 2014: Nelson et al., 2010: Verbruggen et al., 2013: Verbruggen and Logan, 2015).

Here we provide a brief discussion of the independent race model, without the specifics of
 the underlying mathematical basis. However, we recommend that stop-signal users read the
 original modelling papers (e.g. *Logan and Cowan, 1984*) to fully understand the task and the
 main behavioral measures, and to learn more about variants of the race model (e.g. *Boucher et al., 2007; Colonius and Diederich, 2018; Logan et al., 2014, 2015*)

Response inhibition in the stop-signal task can be conceptualized as an independent race 88 between a 'go runner', triggered by the presentation of a go stimulus, and a 'stop runner', 89 triggered by the presentation of a stop signal (Logan and Cowan, 1984). When the 'stop runner' 90 finishes before the 'go runner', response inhibition is successful and no response is emitted 91 (successful stop trial); but when the 'go runner' finishes before the 'stop runner', response 92 inhibition is unsuccessful and the response is emitted (unsuccessful stop trial). The independent 93 race model mathematically relates (a) the latencies (RT) of responses on unsuccessful stop trials; 94 (b) RTs on go trials; and (c) the probability of responding on stop-signal trials [p(respond|stop 95 signal)] as a function of stop-signal delay (yielding 'inhibition functions'). Importantly, the 96 independent race model provides methods for estimating the covert latency of the stop 97 process (stop-signal reaction time; SSRT). These estimation methods are described in Materials 98 and Methods. 99

101 102

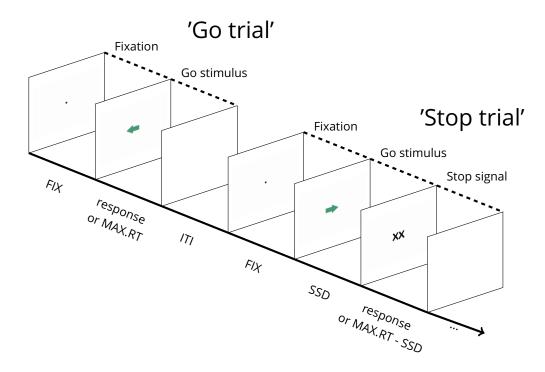

Figure 1. Depiction of the sequence of events in a stop-signal task (see https://osf.io/rmqaw/ for open-source software to execute the task). In this example, participants respond to the direction of green arrows (by pressing the corresponding arrow key) in the go task. On one fourth of the trials, the arrow is replaced by 'XX' after a variable stop-signal delay (FIX = fixation duration; SSD = stop-signal delay; MAX.RT = maximum reaction time; ITI = intertrial interval).

- Recommendation 1: Use an appropriate go task
- 112 Standard two-choice reaction time tasks (e.g. in which participants have to discriminate between
- ¹¹³ left and right arrows) are recommended for most purposes and populations. When very simple go
- 114 tasks are used, the go stimulus and the stop signal will closely overlap in time (because the SSD has
- to be very short to still allow for the possibility to inhibit a response), leading to violations of the
- race model as stop-signal presentation will interfere with encoding of the go stimulus. Substantially
- increasing the difficulty of the go task (e.g. by making the discrimination much harder) might also
- ¹¹⁸ influence the stop process (e.g. the underlying latency distribution or the probability that the stop ¹¹⁹ process is triggered). Thus, very simple and very difficult go tasks should be avoided unless the
- process is triggered). Thus, very simple and very difficult go tasks should be avoided unless the researcher has theoretical or methodological ¹ reasons for using them. While two-choice tasks are
 - the most common, we note that the 'anticipatory response' variant of the stop-signal task (in which
- the most common, we note that the 'anticipatory response' variant of the stop-signal task (in which participants have to press a key when a moving indicator reaches a stationary target) also holds
- number / a a lourisson at al. 2017)
- promise (e.g. *Leunissen et al., 2017*).

124 Recommendation 2: Use a salient stop signal

- SSRT is the overall latency of a chain of processes involved in stopping a response, including the
- detection of the stop signal. Unless researchers are specifically interested in such perceptual
- ¹²⁷ or attentional processes, salient, easily detectable stop signals should be used ². Salient stop
- signals will reduce the relative contribution of perceptual (afferent) processes to the SSRT, and the
- ¹²⁹ probability that within- or between-group differences can be attributed to them. Salient stop signals

¹For example, simple detection tasks have been used in animal studies. To avoid responses before the go stimulus is presented or close overlap between the presentation of go stimulus and stop signal, the intertrial interval can be drawn from a random exponential distribution. This will make the occurrence of the go stimulus unpredictable, resulting in longer RTs on go trials.

²When auditory stop signals are used, these should not be too loud either, as very loud (i.e. >80 dB) auditory stimuli may produce a startle reflex.

- ¹³⁰ might also reduce the probability of a 'trigger failures' on stop trials (see Box 2).
- Recommendation 3: Present stop signals on a minority of trials
- ¹³² When participants strategically wait for a stop signal to occur, the nature of the stop-signal process
- and task change (complicating the comparison between conditions or groups; e.g. SSRT group
- differences might be caused by differential slowing or strategic adjustments). Importantly, SSRT
- estimates will also become less reliable when participants wait for the stop-signal to occur (*Ver*-
- *bruggen et al., 2013*, see also Figure 2 and Appendix 2). Such waiting strategies can be discouraged
- by reducing the overall probability of a stop signal. For standard stop-signal studies, 25% stop
- ¹³⁸ signals is recommended. When researchers prefer a higher percentage of stop signals, additional
- ¹³⁹ measures to minimize slowing are required (see Recommendation 5).
- Recommendation 4: Use the tracking procedure to obtain a broad range of stop-signal
 delays
- If participants can predict when a stop signal will occur within a trial, they might also wait for it. 142 Therefore, a broad range of SSDs is required. The stop-signal delay can be continuously adjusted via 143 a standard adaptive tracking procedure: SSD increases after each successful stop, and decreases 144 after each unsuccessful stop; this converges on a probability of responding [p(respond|stop signal)] 145 ≈ 50 Many studies adjust SSD in steps of 50 ms (which corresponds to three screen 'refreshes' for 146 60-Hz monitors). When step size is too small – e.g. 16 ms – the tracking may not converge in short 147 experiments, whereas it may not be sensitive enough if step size is too large. Importantly, SSD 148 should decrease after all responses on unsuccessful stop trials; this includes premature responses 149 on unsuccessful stop trials (i.e. responses executed before the stop signal was presented) and 150 choice errors on unsuccessful stop trials (e.g. when a left go response would have been executed 151 on the stop-signal trial depicted in Figure 1, even though the arrow was pointing to the right). 152
- An adaptive tracking procedure typically results in a sufficiently varied set of SSD values. An additional advantage of the tracking procedure is that fewer stop-signal trials are required to obtain a reliable SSRT estimate (*Band et al., 2003*). Thus, the tracking procedure is recommended for standard applications.
- Recommendation 5: Instruct participants not to wait and include block-based feedback
 In human studies, task instructions should also be used to discourage waiting. At the very least,
 participants should be told that "[they] should respond as quickly as possible to the go stimulus and not
 wait for the stop signal to occur" (or something along these lines). To adults, the tracking procedure
- (if used) can also be explained to further discourage a waiting strategy (i.e. inform participants that
- the probability of an unsuccessful stop trial will approximate .50, and that SSD will increase if they
 gradually slow their responses).
- Inclusion of a practice block in which adherence to instructions is carefully monitored is recom mended. In certain populations, such as young children, it might furthermore be advisable to start
 with a practice block without stop signals to emphasize the importance of the go component of the
 task.
- Between blocks, participants should also be reminded about the instructions. Ideally, this is combined with block-based feedback, informing participants about their mean RT on go trials, number of go omissions (with a reminder that this should be 0), and p(respond|signal) (with a reminder that this should be close to .50). The feedback could even include an explicit measure of response slowing.
- 173 Recommendation 6: Include sufficient trials
- The number of stop-signal trials varies widely between studies. Our novel simulation results (see
- ¹⁷⁵ Figure 2 and Appendix 2) indicate that reliable and unbiased SSRT group-level estimates can be

¹⁷⁶ obtained with 50 stop trials ³, but only under 'optimal' or very specific circumstances (e.g. when

the probability of go omissions is low and the go-RT distribution is not strongly skewed). Lower

trial numbers (here we tested 25 stop signals) rarely produced reliable SSRT estimates (and the

number of excluded subjects – see Figure 2 – was much higher). Thus, as a general rule of thumb,

we recommend to have at least 50 stop signals for standard group-level comparisons. However, it

181 should again be stressed that this may not suffice to obtain reliable individual-182 required for e.g. individual-differences research or diagnostic purposes)

required for e.g. individual-differences research or diagnostic purposes).
 Thus, our simulations reported in Appendix 2 suggest that reliability increases with number of
 trials. However in some clinical populations, adding trials may not always be possible (e.g. when

patients cannot concentrate for a sufficiently long period of time), and might even be counterproduc-

tive (as strong fluctuations over time can induce extra noise). Our simulations reported in Appendix

¹⁸⁷ 3 show that for standard group-level comparisons, researchers can compensate for lower trial

numbers by increasing sample size. Above all, we strongly encourage researchers to make in-

¹⁸⁹ formed decisions about number of trials and participants, aiming for sufficiently-powered

¹⁹⁰ **studies**. The accompanying open-source simulation code can be used for this purpose.

¹⁹¹ When and how to estimate SSRT

Recommendation 7: Do not estimate the SSRT when the assumptions of the race model
 are violated

SSRTs can be estimated based on the independent race model, which assumes an independent
 race between a go and a stop runner (Box 1). When this independence assumption is (seriously)

violated, SSRT estimates become unreliable (*Band et al., 2003*). Therefore, the assumption should

¹⁹⁷ be checked. This can be done by comparing the mean RT on unsuccessful stop trials with the

mean RT on go trials. Note that this comparison should include all trials with a response (including

¹⁹⁹ choice errors and premature responses), and it should be done for each participant and condition

200 separately. SSRT should not be estimated when RT on unsuccessful stop trials is numerically longer

than RT on go trials (see also, table 1 in Appendix 2). More formal and in-depth tests of the race

model can be performed (e.g. examining probability of responding and RT on unsuccessful stop

trials as a function of delay); however, a large number of stop trials is required for such tests to be

²⁰⁴ meaningful and reliable.

Recommendation 8: If using a non-parametric approach, estimate SSRT using the integra tion method (with replacement of go omissions)

Different SSRT estimation methods have been proposed (see Materials and Methods). When the tracking procedure is used, the 'mean estimation' method is still the most popular (presumably because it is very easy to use). However, the mean method is strongly influenced by the right tail

(skew) of the go RT distribution (see Appendix 2 for examples), as well as by go omissions (i.e. go

trials on which no response is executed). The simulations reported in Appendix 2 and summarized

in Figure 2 indicate that the integration method (which replaces go omissions with the maximum

213 RT in order to compensate for the lacking response) is generally less biased and more reliable than

the mean method when combined with the tracking procedure. Unlike the mean method, the

integration method also does not assume that p(respond|signal) is exactly .50 (an assumption that

is often not met in empirical data). Therefore, we recommend the use of the integration method

(with replacement of omissions on go trials) when non-parametric methods are used. We provide

software and the source code for this estimation method (and all other recommended measures;
 Recommendation 12).

Please note that some parametric SSRT estimation methods are less biased than even the best non-parametric methods and avoid other problems that can beset them (see Box 2), but can be

³With 25% stop signals in an experiment, this amounts to 200 trials in total. Usually, this corresponds to an experiment of 7-10 minutes including breaks.

Box 2. Failures to trigger the stop process

The race model assumes that the go runner is triggered by the presentation of the go stimulus. 239 and the stop runner by the presentation of the stop signal. However, go omissions (i.e. go trials 240 without a response) are often observed in stop-signal studies. Our preferred SSRT method 241 compensates for such go omissions (see Materials and Methods). However, turning to the 242 stopping process, studies using fixed SSDs have found that p(respond | signal) at very short 243 delays (including SSD = 0 ms, when go and stop are presented together) is not always zero; 244 this finding indicates that the stop runner may also not be triggered on all stop trials ('trigger 245 failures'). 246

The non-parametric estimation methods described in Materials and Methods (see also Ap-247 pendix 2) will overestimate SSRT when trigger failures are present on stop trials (Band et al., 248 2003). Unfortunately, these estimation methods cannot determine the presence or absence 249 of trigger failures on stop trials. In order to diagnose in how far trigger failures are present 250 in their data, researchers can include extra stop signals that occur at the same time of the 251 go stimulus (i.e. SSD = 0, or shortly thereafter). Note that this number of zero-SSD trials 252 should be sufficiently high to detect (subtle) within- or between-group differences in trigger 253 failures. Furthermore, p(respond | signal) should be reported separately for these short-SSD 254 trials, and these trials should not be included when calculating mean SSD or estimating SSRT 255 (see Recommendation 1 for a discussion of problems that arise when SSDs are very short). 256 Alternatively, researchers can use a parametric method to estimate SSRT. Such methods de-257 scribe the whole SSRT distribution (unlike the non-parametric methods that estimate summary 258 measures, such as the mean stop latency). Recent variants of such parametric methods also 259 provide an estimate of the probability of trigger failures on stop trials (for the most recent 260 version and specialized software, see *Matzke et al.*, 2019). 261

harder for less technically adept researchers to use, and they may require more trials (see *Matzke et al.*, *2018*, for a discussion).

224 Recommendation 9: Refrain from estimating SSRT when the probability of responding on

stop-signal trials deviates substantially from .50 or when the probability of omissions on

226 go trials is high

²²⁷ Even though the preferred integration method (with replacement of go omissions) is less influenced

by deviations in p(respond|signal) and go omissions than other methods, it is not completely immune to them either (Figure 2 and Appendix 2). Previous work suggests that SSRT estimates are most reliable (*Band et al., 2003*) when probability of responding on a stop trial is relatively close to .50. Therefore, we recommend that researchers refrain from estimating individual SSRTs when p(respond|signal) is lower than .25 or higher than .75 (*Congdon et al., 2012*). Reliability of the

estimates is also influenced by go performance. As the probability of a go omission increases, SSRT estimates also become less reliable. Figure 2 and the resources described in Appendix 3 can be

estimates also become less reliable. Figure 2 and the resources described in Appendix 3 can be used to determine an acceptable level of go omissions at a study level. Importantly, researchers

used to determine an acceptable level of go omissions at a study level. Importantly, research

should decide on these cut-offs or exclusion criteria before data collection has started.

²⁶² How to report stop-signal experiments

Recommendation 10: Report the methods in enough detail

- ²⁶⁴ The description of every stop-signal study should include the following information (which can be
- ²⁶⁵ presented in Supplementary Materials in case of journal restrictions):
- Stimuli and materials
- Properties of the go stimuli, responses, and their mapping

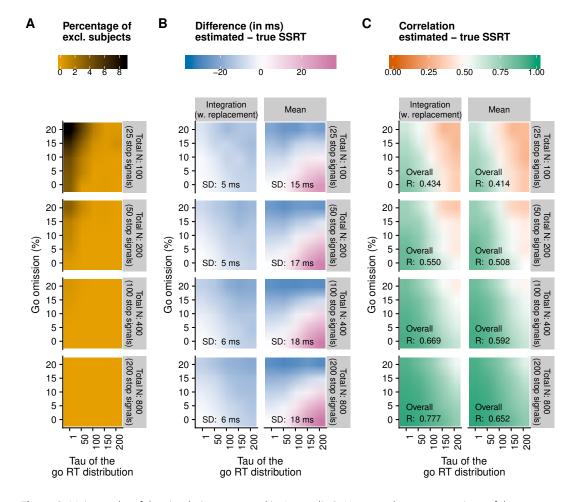

Figure 2. Main results of the simulations reported in Appendix 2. Here we show a comparison of the integration method (with replacement of go omissions) and the mean method, as a function of percentage of go omissions, skew of the RT distribution (τ_{go}), and number of trials. Appendix 2 provides a full overview of all methods. **A**: The number of excluded 'participants' (RT on unsuccessful stop trials > RT on go trials). As this check was performed before SSRTs were estimated (see Recommendation 7), the number was the same for both estimation methods. **B**: The average difference between the estimated and true SSRT (positive values = overestimation; negative values = underestimation). SD = standard deviation of the difference scores (per panel). **C**: Correlation between the estimated and true SSRT (higher values = more reliable estimate). Overall R = correlation when collapsed across percentage of go omissions and τ_{go} . (Please note that the overall correlation does not necessarily correspond to the average of individual correlations.)

268	 Properties of the stop signal Equipment used for testing
269	
270	• The procedure
271	- The number of blocks (including practice blocks)
272	 The number of go and stop trials per block Detailed description of the randomization (e.g., is the order of go and stop trials fully.
273	 Detailed description of the randomization (e.g. is the order of go and stop trials fully randomized or pseudo-randomized?)
274 275	 Detailed description of the tracking procedure (including start value, step size, minimum
275	and maximum value) or the range and proportion of fixed stop-signal delays.
277	 Timing of all events. This can include intertrial intervals, fixation intervals (if applicable),
278	stimulus-presentation times, maximum response latency (and whether a trial is aborted
279	when a response is executed or not), feedback duration (in case immediate feedback is
280	presented), etc.
281	 A summary of the instructions given to the participant, and any feedback-related infor-
282	mation (full instructions can be reported in Supplementary Materials).
283	 Information about training procedures (e.g. in case of animal studies)
284	The analyses
285	 Which trials were included when analyzing go and stop performance
286	- Which SSRT estimation method was used (see Materials and Methods), providing addi-
287	tional details on the exact approach (e.g. whether or not go omissions were replaced;
288	how go and stop trials with a choice errors–e.g. left response for right arrows–were
289	handled; how the nth quantile was estimated; etc.)
290	 Which statistical tests were used for inferential statistics
291	This list can serve as a check-list for authors and reviewers. We also encourage researchers to
292	share their software and materials (e.g. the actual stimuli).
	Becommandation 11: Benert possible evolutions in anough detail
293	Recommendation 11: Report possible exclusions in enough detail As outlined above, researchers should refrain from estimating SSRT when the independence
294 295	assumptions are seriously violated or when sub-optimal task performance might otherwise compro-
295	mise the reliability of the estimates. The number of participants for whom SSRT was not estimated
297	should be clearly mentioned. Ideally, dependent variables which are directly observed (see Rec-
298	ommendation 12) are separately reported for the participants that are not included in the SSRT
299	analyses.
300	Researchers should also clearly mention any other exclusion criteria (e.g. outliers based on
301	distributional analyses, acceptable levels of go omissions, etc.), and whether those were set a-priori
302	(analytic plans can be preregistered on a public repository, such as Open Science Framework; Nosek
303	et al., 2018).
304	Recommendation 12: Report all relevant behavioral data
305	All stop-signal studies should (at least) report the following descriptive statistics (see Appendix 4 for
306	a description of all labels):
	Probability of go omissions (no response)
307	 Probability of choice errors on go trials
308 309	 RT on go trials (mean or median). We recommend to report intra-subject variability as well
310	(especially for clinical studies).
311	 Probability of responding on a stop-signal trial (for each SSD when fixed delays are used)
312	• Average stop-signal delay (when the tracking procedure is used); depending on the set-up, it
313	is advisable to report (and use) the 'real' SSDs (e.g. for visual stimuli, the requested SSD may
314	not always correspond to the real SSD due to screen constraints).

- Stop-signal reaction time
- RT of go responses on unsuccessful stop trials

³¹⁷ These should be reported for each group or condition separately. As noted above (Recommen-

dation 7), additional checks of the independent race model can be reported when the number of

319 stop-signal trials is sufficiently high.

Finally, we encourage researchers to share their anonymized raw (single-trial) data when possible (in accordance with the FAIR data guidelines; *Wilkinson et al., 2016*).

322 Conclusion

Response inhibition and impulse control are central topics in various fields of research, including neuroscience, psychiatry, psychology, neurology, pharmacology, and behavioral sciences, and the stop-signal task has become an essential tool in their study. If properly used, the task can reveal unique information about the underlying neuro-cognitive control mechanisms. By providing clear recommendations, and open-source resources, this paper aims to further increase the quality of research in the response-inhibition and impulse-control domain and significantly accelerate its progress across the various important domains in which it is routinely applied.

330 Materials and Methods

³³¹ The independent race model (Box 1) provides two common 'non-parametric' methods for estimating

332 SSRT: the integration method and the mean method. Both methods have been used in slightly

different flavors in combination with the SSD tracking procedure (see Recommendation 4). Here we

discuss the two most typical estimation variants, which we further scrutinized in our simulations

(Appendix 2). We refer the reader to Appendix 2 and 3 for a detailed description of the simulations.

³³⁶ Integration method (with replacement of go omissions)

In the integration method, the point at which the stop process finishes (Box 1) is estimated by 337 'integrating' the RT distribution and finding the point at which the integral equals p(respond signal). 338 The finishing time of the stop process corresponds to the nth RT, with n = the number of RTs in 339 the RT distribution of go trials multiplied by p(respond | signal). When combined with the tracking 340 procedure, overall p(respond | signal) is used. For example, there are 200 go trials, and overall 341 p(respond | signal) is .45, then the nth RT is the 90th fastest go RT. SSRT can then be estimated by 342 subtracting mean SSD from the nth RT. To determine the nth RT, all go trials with a response are 343 included (including go trials with a choice error and go trials with a premature response). Importantly, go 344 omissions (i.e. go trials on which the participant did not respond before the response deadline) are 345 assigned the maximum RT in order to compensate for the lacking response. Premature responses 346 on unsuccessful stop trials (i.e. responses executed before the stop signal is presented) should also 347 be included when calculating p(respond | signal) and mean SSD (as noted in Recommendation 4. 3/18 SSD should also be adjusted after such trials). This version of the integration method produces 340 the most reliable and least biased (non-parametric) SSRT estimates (Appendix 2). 350

351 The mean method

The mean method uses the mean of the inhibition function (which describes the relationship 352 between p(respond | signal) and SSD). Ideally, this mean corresponds to the average SSD obtained 353 with the tracking procedure when p(respond | signal) = .50 (and often this is taken as a given despite 354 some variation). In other words, the mean method assumes that the mean RT equals SSRT + mean 355 SSD, so SSRT can be estimated easily by subtracting mean SSD from mean RT on go trials when the 356 tracking procedure is used. The ease of use has made this the most popular estimation method. 357 However, our simulations show that this simple version of the mean method is biased and 358 generally less reliable than the integration method with replacement of go omissions. 350

428 Appendix 2

Race model simulations to determine estimation bias and reliability of SSRT estimates

Simulation procedure

To compare different SSRT estimation methods, we ran a set of simulations which simulated performance in the stop-signal task based on assumptions of the independent race model: on stop-signal trials, a response was deemed to be stopped (successful stop) when the RT was larger than SSRT + SSD; a response was deemed to be executed (unsuccessful stop) when RT was smaller than SSRT + SSD. Go and stop were completely independent.

All simulations were done using R (*R Core Team, 2017*, version 3.4.2). Latencies of the go and stop runners were sampled from an ex-Gaussian distribution, using the rexGaus function (*Rigby and Stasinopoulos, 2005*, version 5.1.2). The ex-Gaussian distribution has a positively skewed unimodal shape and results from a convolution of a normal (Gaussian) distribution and an exponential distribution. It is characterized by three parameters: μ (mean of the Gaussian component), σ (SD of Gaussian component), and τ (both the mean and SD of the exponential component). The mean of the ex-Gaussian distribution = $\mu + \tau$, and variance = $\sigma^2 + \tau^2$. Previous simulation studies of the stop-signal task also used ex-Gaussian distributions to model their reaction times (e.g. *Band et al., 2003; Verbruggen et al., 2013; Matzke et al., 2019*).

For each simulated 'participant', μ_{go} of the ex-Gaussian go RT distribution was sampled from a normal distribution with mean = 500 (i.e. the population mean) and SD = 50, with the restriction that it was larger than 300 (see *Verbruggen et al., 2013*, for a similar procedure). σ_{go} was fixed at 50, and τ_{go} was either 1, 50, 100, 150, and 200 (resulting in increasingly skewed distributions). The RT cut-off was set at 1,500 ms. Thus, go trials with an RT > 1,500 ms were considered go omissions. For some simulations, we also inserted extra go omissions, resulting in five 'go omission' conditions: 0% inserted go omissions (although the occasional go omission was still possible when τ_{go} was high), 5%, 10%, 15%, or 20%. These go omissions were randomly distributed across go and stop trials. For the 5%, 10%, 15%, and 20% go-omission conditions, we checked first if there were already go omissions due to the random sampling from the ex-Gaussian distribution. If such 'go omissions' occurred 'naturally', fewer 'artificial' omissions were inserted.

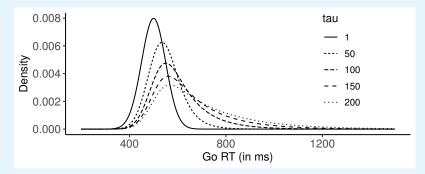

Figure 1. Examples of ex-Gaussian (RT) distributions used in our simulations. For all distributions, μ_{go} = 500 ms, and σ_{go} = 50 ms. τ_{go} was either 1, 50, 100, 150, and 200 (resulting in increasingly skewed distributions). Note that the 'artificially' inserted omissions are not depicted in the figure.

For each simulated 'participant', μ_{stop} of the ex-Gaussian SSRT distribution was sampled from a normal distribution with mean = 200 (i.e. the population mean) and SD = 20, with the restriction that it was larger than 100. σ stop and τ stop were fixed at 20 and 10, respectively.

The total number of trials simulated per participant was either 100, 200, 400, or 800, whereas the probability of a stop-signal was fixed at .25; thus, the number of stop trials was 25, 50, 100, or 200, respectively. Overall, this resulted in 5 (go omission: 0, 5, 10, 15, or 20%) x 5 (τ_{go} : 1, 50, 100, 150, 200) x 4 (total number of trials: 100, 200, 400, 800) conditions. For each condition, we simulated 1000 participants. Overall, this resulted in 100,000 participants (and 375,000,000 trials).

The code used for the simulations and all simulated data can be found on Open Science Framework (https://osf.io/rmqaw/).

Analyses

We performed three sets of analyses. First, we checked if RT on unsuccessful stop trials was numerically shorter than RT on go trials. Second, we estimated SSRTs using the two estimation methods described in the main manuscript (Materials and Methods), and two other methods that have been used in the stop-signal literature. The first one is a variant of the integration method described in the main manuscript. The main difference is the exclusion of go omissions (and sometimes choice errors on unsuccessful stop trials) from the go RT distribution when determining the nth RT. The second variant also does not assign go omissions the maximum RT. Rather, this method adjusts p(respond | signal) to compensate for go omissions (*Tannock et al., 1989*):

$$p(respond | signal)_{adjusted} = 1 - \frac{p(inhibit | signal) - p(omission | go)}{1 - p(omission | go)}$$

The nth RT is then determined using the adjusted p(respond|signal) and the distribution of RTs of all go trials with a response.

Thus, we estimated SSRT using four different methods: (1) integration method with replacement of go omissions; (2) integration method with exclusion of go omissions; (3) integration method with adjustment of p(respond | signal); and (4) the mean method. For each estimation method and condition (go omission x τ_{go} x number of trials), we calculated the difference between the estimated SSRT and the actual SSRT; positive values indicate that SSRT is overestimated, whereas negative values indicate that SSRT is underestimated. For each estimation method, we also correlated the true and estimated values across participants; higher values indicate more reliable SSRT estimates.

In the main manuscript, we provide a detailed overview of (1) the integration method with replacement of go omissions and (2) the mean method: as described below, the integration method with replacement of go omissions was the least biased and most reliable, but we also show the mean method to further highlight the issues that arise when this (still popular) mean method is used.

Results

All figures were produced using the ggplot2 package (version 3.1.0 *Wickham, 2016*). The number of excluded 'participants' (i.e. RT on unsuccessful stop trials > RT on go trials) is presented in Figure 2 of the main manuscript. Note that these are only apparent violations of the independent race model, as go and stop were always modelled as independent runners. Instead, the longer RTs on unsuccessful stop trials result from estimation uncertainty associated with estimating mean RTs using scarce data. However, as true SSRT of all participants was known, we could nevertheless compare the SSRT bias for included and excluded participants. As can be seen in the table below, estimates were generally much more biased for 'excluded' participants than for 'included' participants. Again this indicates that **extreme data are more likely to occur when the number of trials is low**.

To further compare differences between estimated and true SSRTs for the included participants, we used 'violin plots'. These plots show the distribution and density of SSRT difference values. We created separate plots as a function of the total number of trials (100, 200, 400, and 800), and each plot shows the SSRT difference as a function of estimation method, percentage of go omissions, and τ_{go} (i.e. the skew of the RT distribution on go trials). The plots can be found below. The first important thing to note is that the scales differ between subplots. This was done intentionally, as the distribution of difference scores was wider when the number of trials was lower (with fixed scales, it is difficult to detect meaningful differences between estimation methods and conditions for higher trial numbers; i.e. Panels C and D). In other words, **low trial numbers will produce more variable and less reliable SSRT estimates**.

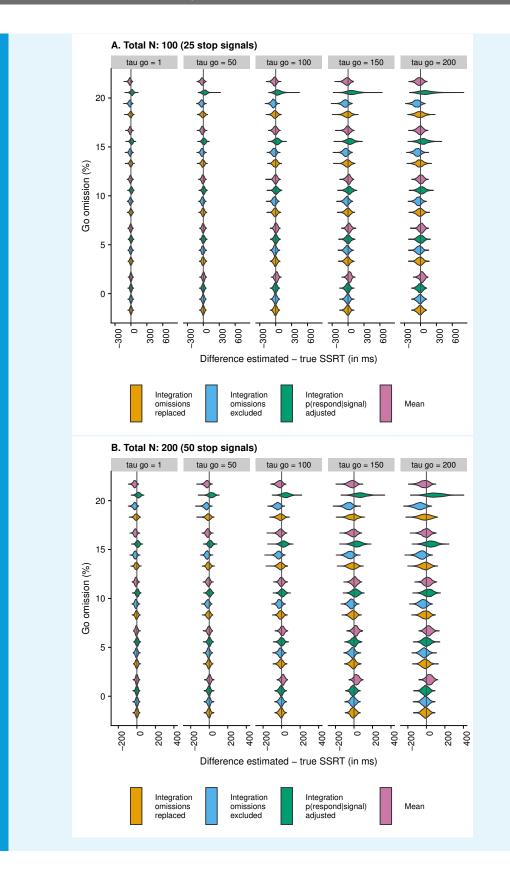

Second, the violin plots show that **SSRT estimates are strongly influenced by an increasing percentage of go omissions**. The figures show that the integration method with replacement of go omissions, integration method with exclusion of go omissions, and the mean method all have a tendency to underestimate SSRT as the percentage of go omissions increases; importantly, *this underestimation bias is most pronounced for the integration method with exclusion of go omissions*. By contrast, the integration method which uses the adjusted p(respond | signal) will overestimate SSRT when go omissions are present; compared with the other methods, this bias was the strongest in absolute terms.

Consistent with previous work (*Verbruggen et al., 2013*), **skew of the RT distribution also strongly influenced the estimates**. SSRT estimates were generally more variable as τ_{go} increased. When the probability of a go omission was low, the integration methods showed a small underestimation bias for high levels of τ_{go} , whereas the mean method showed a clear overestimation bias for high levels of τ_{go} . In absolute terms, this overestimation bias for the mean method was more pronounced than the underestimation bias for the integration methods. For higher levels of go omissions, the pattern became more complicated as the various biases started to interact. Therefore, we also correlated the true SSRT with the estimated SSRT to compare the different estimation methods.

To calculate the correlation between true and estimated SSRT for each method, we collapsed across all combinations of τ_{go} , go omission rate, and number of trials. **The correlation (i.e. reliability of the estimate) was highest for the integration method with replacement of go omissions (r = .57)**, intermediate for the mean method (r = .53) and the integration method with exclusion of go errors (r = .51), and lowest for the integration method using adjusted p(respond|signal) (r = .43).

Estimation method	Included	Excluded
Integration with replacement of go omissions	-6.4	-35.8
Integration without replacement of go omissions	-19.4	-48.5
Integration with adjusted p(respond signal)	12.5	-17.4
Mean	-16.0	-46.34

Table 1. The mean difference between estimated and true SSRT for participants who were included in the main analyses and participants who were excluded (because average RT on unsuccessful stop trials > average RT on go trials). We did this only for τ_{go} = 1 or 50, p(go omission) = 10, 15, or 20, and number of trials = 100 (i.e. when the number of excluded participants was high; see Panel A, Figure 2 of the main manuscript).

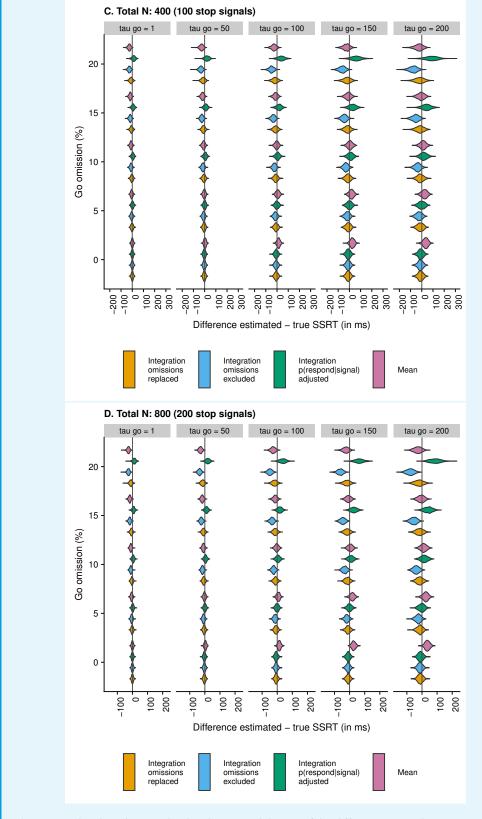

Figure 2. Violin plots showing the distribution and density of the difference scores between estimated and true SSRT as a function of condition and estimation method. Values smaller than zero indicate underestimation; values larger than zero indicate overestimation.

Race model simulations to determine achieved power Simulation procedure

To determine how different parameters affected the power to detect SSRT differences, we simulated 'experiments'. We used the same general procedure as described in Appendix 2. In the example described below, we used a simple between-groups design with a control group and an experimental group.

For each simulated 'participant' of the 'control group', μ_{go} of the ex-Gaussian go RT distribution was sampled from a normal distribution with mean = 500 (i.e. the population mean) and SD = 100, with the restriction that it was larger than 300. σ_{go} and τ_{go} were both fixed at 50, and the percentage of (artificially inserted) go omissions was 0% (see Appendix 2). μ_{stop} of the ex-Gaussian SSRT distribution was also sampled from a normal distribution with mean = 200 (i.e. the population mean) and SD = 40, with the restriction that it was larger than 100. σ stop and τ stop were fixed at 20 and 10, respectively. Please note that the SDs for the population means were higher than the values used for the simulations reported in Appendix 2 to allow for extra between-subjects variation in our groups.

For the 'experimental group', the go and stop parameters could vary across 'experiments'. μ_{go} was sampled from a normal distribution with population mean = 500, 525, or 575 (SD = 100). σ_{go} was 50, 52.5, or 57.5 (for population mean of μ_{go} = 500, 525, and 575, respectively), and τ_{go} was either 50, 75, or 125 (also for population mean of μ_{go} = 500, 525, and 575, respectively). Remember that the mean of the ex-Gaussian distribution = $\mu + \tau$ (Appendix 2). Thus, mean go RT of the experimental group was either 550 ms (500 + 50, which is the same as the control group), 600 (525+75), or 700 (575 + 125). The percentage of go omissions for the experimental group was either 0% (the same as the experimental group), 5% (for μ_{go} = 525) or 10% (for μ_{go} = 575).

Parameters of go distribution	Control	Experimental 1	Experimental 2	Experimental 3
μ_{go}	500	500	525	575
σ_{go}	50	50	52.5	57.5
$ au_{go}$	50	50	75	125
go omission	0	0	5	10

Table 1. Parameters of the go distribution for the control group and the three experimental conditions. SSRT of all experimental groups differed from SSRT in the control group (see below)

 μ_{stop} of the 'experimental-group' SSRT distribution was sampled from a normal distribution with mean = 210 or 215 (SD = 40). σ_{stop} was 21 or 21.5 (for μ_{stop} = 210 and 215, respectively), and τ_{stop} was either 15 (for population mean of μ_{stop} = 210) or 20 (for population mean of μ_{stop} = 215). Thus, mean SSRT of the experimental group was either 225 ms (210 + 15; corresponding to a medium effect size. Cohen's d \approx .50-55. Note that the exact value could differ slightly between simulations as random samples were taken) or 235 (215 + 20; corresponding to a large effect size. Cohen's d \approx .85-90). SSRT varied independently from the go parameters (i.e. $\mu_{go} + \tau_{go'}$ and % go omissions).

The total number of trials per experiment was either 100 (25 stop trials), 200 (50 stop trials) or 400 (100 stop trials). Other simulation parameters were the same as those described in Appendix 2. Overall, this resulted in 18 different combinations: 3 (go difference between control and experimental; see Table 1 above) x 2 (mean SSRT difference between control

combination, we simulated 5000 'pairs' of subjects.

and experimental: 15 or 30) x 3 (total number of trials: 100, 200 or 400). For each parameter

The code and results of the simulations are available via the Open Science Framework (https://osf.io/rmqaw/); stop-signal users can adjust the scripts (e.g. by changing parameters or even the design) to determine the required sample size given some consideration about the expected results. Importantly, the present simulation code provides access to a wide set of parameters (i.e. go omission, parameters of the go distribution, and parameters of the SSRT distribution) that could differ across groups or conditions.

Analyses

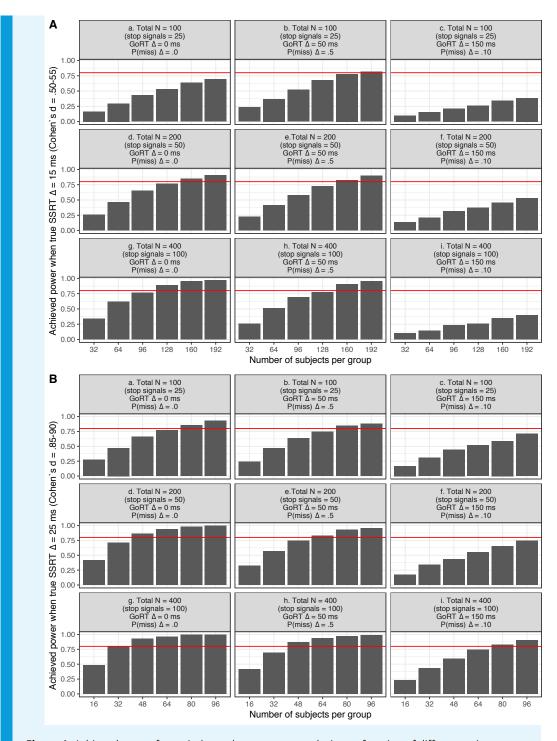

SSRTs were estimated using the integration method with replacement of go omissions (i.e. the method that came out on top in the other set of simulations). Once the SSRTs were estimated, we randomly sampled 'pairs' to create the two groups for each 'experiment'. For the 'medium' SSRT difference (i.e. 210 vs. 225 ms), group size was either 32, 64, 96, 128, 160, or 192 (the total number of participants per experiment was 2x the group size). For the 'large' SSRT difference (i.e. 210 vs. 235 ms), group size was either 16, 32, 48, 64, 80, or 96 (the total number of participants per experiment was 2x the group size). For each sample size and parameter combination (see above), we repeated this procedure 1,000 times (or 1,000 experiments).

For each experiment, we subsequently compared the estimated SSRTs of the control and experiment groups with an independent-samples t-test (assuming unequal variances). Then we determined for each sample size x parameter combination the proportion of t-tests that were significant (with α = .05).

Results

The figure below plots achieved power as a function of sample size (per group), experimental vs. control group difference in true SSRT, and group differencess in go performance. Note that if true and estimated SSRTs would exactly match (i.e. estimations reliability = 1), approximately 58 participants per group would be required to detect a medium-sized true SSRT difference with power = .80 (i.e. when Cohen's d \approx .525), and 22 participants per group for a large-sized true SSRT difference (Cohen's d \approx .875).

Inspection of the figure clearly reveals that achieved power generally increases when sample size and number of trials increase. Obviously achieved power is also strongly dependent on effect size (Panel A vs. B). Interestingly, the figure also shows that the ability to detect SSRT differences is reduced when the RT distributions of the groups differ substantially (see second and third columns of Panel A). As noted in the main manuscript and Appendix 2, even the integration method (with replacement of go omissions) is not immune to changes in the RT distribution. More specifically, SSRT will be underestimated when the RT distribution is skewed (note that all other approaches produce an even stronger bias). In this example, the underestimation bias will reduce the observed SSRT difference (as the underestimation bias is stronger for the experimental group than for the control group). Again, this highlights the need to encourage consistent fast responding (reducing the right-end tail of the distribution).

646 648 **Figure 1.** Achieved power for an independent two-groups design as function of differences in go omission, go distribution, SSRT distribution, and the number of trials in the 'experiments'.

651

Overview of the main labels and common alternatives

Label	Description	Common alternative la- bels
Stop-signal task	The task used to measure response inhibition in the lab. Consists of a go com- ponent (e.g. a two-choice discrimination task) and a stop component (suppress- ing the response when an extra signal appears).	Stop-signal reaction time task, stop-signal paradigm, countermanding task
Go trial	On these trials (usually the majority), participants re- spond to the go stimulus as quickly and accurately as possible (e.g. left arrow = left key, right arrow = right key).	No-signal trial, no-stop- signal trial
Stop trial	On these trials (usually the minority), an extra signal is presented after a vari- able delay, instructing par- ticipants to stop their re- sponse to the go stimulus.	Stop-signal trial, signal trial
Successful stop trial	On these stop trials, the participants successfully stopped (inhibited) their go response.	Stop-success trial, signal- inhibit trial, canceled trial
Unsuccessful stop trial	On these stop-signal trials, the participants could not inhibit their go response; hence, they responded de- spite the (stop-signal) in- struction not to do so.	Stop-failure trial, signal- respond trial, noncanceled trial, stop error

Label	Description	Common alternative la- bels
Go omission	Go trials without a go re- sponse.	Go-omission error, misses, missed responses
Choice errors on go trials	Incorrect response on a go trial (e.g. the go stimulus re- quired a left response but a right response was exe- cuted).	(Go) errors, incorrect (go or no-signal) trials
Premature response on a go trial	A response executed be- fore the presentation of the go stimulus on a go trial. This can happen when go-stimulus presentation is highly predictable in time (and stimulus identity is not relevant to the go task; e.g. in a simple detection task) or when participants are 'impulsive'. Note that re- sponse latencies will be neg- ative on such trials.	
P(respond signal)	Probability of respond- ing on a stop-signal trial. Non-parametric estimation methods (Ma- terials and Methods) use p(respond signal) to determine SSRT.	P(respond), response rate, p(inhibit) = 1- p(respond signal)
Choice errors on unsuccess- ful stop trials	Unsuccessful stop trials on which the incorrect go re- sponse was executed (e.g. the go stimulus required a left response but a right re- sponse was executed).	Incorrect signal-respond tri- als
Premature responses on unsuccessful stop trials	Go responses executed be- fore the stop-signal is pre- sented on a stop-signal trial. Note that this can also include responses ex- ecuted before the presen- tation of the go stimulus (see description premature responses on go trials).	Premature signal-respond
Trigger failures on stop tri- als	Failures to launch the stop process or 'runner' on stop trials (see Box 2 for further discussion).	

Label	Description	Common alternative la- bels
Reaction time (RT) on go tri- als	How long does it take to re- spond to the stimulus on go trials? This corresponds to the finishing time of the go runner in the independent race model.	Go RT, go latency, no-signal RT
Stop-signal delay (SSD)	The delay between the pre- sentation of the go stimulus and the stop-signal	Stimulus-onset asynchrony (SOA)
Stop-signal reaction time (SSRT)	How long does it take to stop a response? SSD + SSRT correspond to the fin- ishing time of the stop run- ner in the independent race model.	Stop latency
RT on unsuccessful stop tri- als	Reaction time of the go response on unsuccessful stop trials	Signal-respond RT, SR-RT (note that this abbreviation is highly similar to the ab- breviation for stop-signal reaction time, which can cause confusion)
